ABSTRACT

Recent effort to test deep learning systems has produced an intuitive and compelling test criterion called neuron coverage (NC), which resembles the notion of traditional code coverage. NC measures the proportion of neurons activated in a neural network and it is implicitly assumed that increasing NC improves the quality of a test suite. In an attempt to automatically generate a test suite that increases NC, we design a novel diversity promoting regularizer that can be plugged into existing adversarial attack algorithms. We then assess whether such attempts to increase NC could generate a test suite that (1) detects adversarial attacks successfully, (2) produces natural inputs, and (3) is unbiased to particular class predictions. Contrary to expectation, our extensive empirical evaluation finds that increasing NC actually makes it harder to generate an effective test suite: higher neuron coverage leads to fewer defects detected, less natural inputs, and more biased prediction preferences. Our results invoke skepticism that neuron coverage may not be a meaningful measure for testing deep neural networks and call for a new test generation technique that considers defect detection, naturalness, and output impartiality in tandem.

ACM Reference Format:

1 INTRODUCTION

Extensive progress in machine learning has enabled computers to model much of the expected behavior with minimal human guidance and has led to its integration into many safety-critical systems [5, 23]. Since all software is prone to unanticipated and undesirable defects, creating test suites and assessing their quality is an important part of building confidence during the software lifecycle.

To assess the test adequacy of neural networks, prior work proposed neuron coverage (NC) [40] and its variants [32, 49]. This notion of NC builds on the intuition of code coverage, whilst recognizing the unique challenges and structures of neural networks. NC describes the proportion of neurons activated beyond a given threshold. The intuition here is that NC captures the magnitude of individual neuron activations independently and thus serves as a proxy for observing model behavior. Based on the implicit assumption that increasing NC can also improve test suite quality, NC was used to guide automated test generation [40, 49] and prior work found preliminary evidence that NC is correlated with defect detection capability [49].

To systematically increase NC during test generation, we develop a novel diversity-promoting regularizer that can be plugged into existing adversarial attack algorithms such as PGD [33] and CW [7]. This regularizer penalizes skewed layer-wise activations to promote more diverse neuron activation distributions. As a result, our regularizer can be added to augment existing adversarial attack methods so that these methods can induce previously inactive neurons to fire and thereby increase NC. While prior work [40, 49] has attempted to improve a few neurons’ activation magnitudes at each optimization step, our diversity-promoting regularizer makes this process more systematic by incorporating NC increase and diversification into the optimization objective.

We then assess the generated test suites using three criteria. The first is defect detection capability, i.e., the ability to detect adversarial attacks. The second is the naturalness of the generated test inputs and we use the Inception Score (IS) [4, 43] and the Fréchet Inception Distance (FID) [16, 36] to assess how realistic the generated test inputs are. The third criteria is output impartiality, the degree to which model predictions are biased (or unbiased) towards particular class labels. Assessing impartiality is inspired by the output-uniqueness test selection criteria [2], as the test suite must exercise diverse output behavior and should not prefer only a few output values. We assess output impartiality using entropy [45].

Equipped with the above evaluation metrics and the novel diversity promoting input generation method, we investigate the trade-offs between neuron coverage, defect detection, naturalness and output impartiality. We study two image classification datasets...
(MNIST and CIFAR10), one autonomous vehicle dataset (Udacity Self-Driving Car), six classification-based DNN models, two regression-based DNN models, and two attack algorithms (CW and PGD). In total, 2095 test suites, over 200,000 images, are generated, where each test suite represents a different configuration of models, datasets, attack algorithms, and hyperparameter combinations used for targeting certain layers and promoting diversity in neuron activations. Our extensive analysis finds that increasing NC actually makes it harder to generate an effective test suite.

1. **Defect Detection**: Only 2 out of 64 experimental results supported the hypothesis that neuron coverage is both strongly and positively correlated with defect detection (i.e., adversarial attack success), whereas 33 were negatively correlated, implying that increasing NC is likely to harm defect detection.

2. **Naturalness**: Only 1 out of 64 experimental results supported the hypothesis that neuron coverage is both strongly and positively correlated with the realism and naturalness of the inputs, whereas 44 were negatively correlated, implying that increasing NC is likely to make the generated test inputs more unnatural.

3. **Output Impartiality**: Only 3 out of 64 experimental results supported the hypothesis that neuron coverage is both strongly and positively correlated with impartiality in output predictions, whereas 21 were negatively correlated. Certain class labels have higher NC by default and the process of increasing NC in fact biases perturbations towards those output class labels.

Our key contributions are summarized as follows:

- We develop a novel regularization technique that can be seamlessly integrated to existing adversarial attack methods to promote neural activation diversity and increase neuron coverage during test suite generation.
- We adopt the Inception Score (IS) [43] and Fréchet Inception Distance (FID) [16] as generic, scalable, and automatic means of evaluating naturalness. We also use Shannon entropy [45] to examine the previously under-investigated issue of output impartiality of model predictions.
- We conduct extensive empirical evaluations to show that neuron coverage is neither positively nor strongly correlated with attack success, input realism, and output impartiality, which we argue are important properties to consider when testing DL systems.
- We put forward the complete code and artifacts to automatically generate test suites and replicate our empirical analysis at [https://doi.org/10.5281/zenodo.3698556](https://doi.org/10.5281/zenodo.3698556)

Overall, our findings invoke skepticism that neuron coverage may not be a meaningful measure for testing deep neural networks. This result is aligned with recent skepticism that, while code coverage remains a widely used test adequacy criterion [6, 22], code coverage may not be correlated with defect detection [21] and thus may not be a meaningful metric by itself.

These findings call for a new test generation method that not only improves defect detection, but also promotes naturalness and output impartiality to create realistic inputs to exercise diverse output behavior. This argument to incorporate additional objectives is aligned with a recent survey of testing ML-based systems [52] that lists multiple desired testing properties, including correctness, model relevance, robustness, security, efficiency, fairness, interpretability, privacy, and surprise adequacy. Satisfying such multiple objectives may necessitate the use of multi-objective search techniques [29] or enable users to easily add domain-specific constraints to guide meaningful input transformation and oracle checking in metamorphic testing [44].

## 2 RELATED WORK

This section reviews related work on DL systems, DNN testing, and adversarial attacks. Work relevant to our methodology is described in greater detail in Section 3.

**Deep Learning Systems.** DNNs have achieved many breakthroughs in the field of artificial intelligence, such as speech recognition [17], image processing [26], statistical machine translation [3], and game playing [46]. Each DNN contains basic computational units called neurons, which are connected with one another via edges of varying importance or weight. Neurons apply a nonlinear activation function to the inner product of their inputs and weights to output a value, which becomes the input to a subsequent neuron. Layers are used to organize the directed connections between neurons and there is always one or more hidden layers between one input and one output layer. Overall, a DNN can be viewed as a meta-function that aggregates the weighted contributions from its neural sub-functions to map some input into some target output. Suboptimally set weights make the DL system vulnerable to erroneous behaviors and the opacity of these numerically-derived rules make them difficult to understand and debug.

**DNN Testing.** With the success of deep learning, there emerged a line of research into testing DNNs by leveraging the ideas in traditional software testing methods [14, 34]. We discuss several of the most relevant DNN testing methods that utilize the NC-based criteria as follows.

DeepXplore [40] is a white-box differential testing algorithm that leverages NC to guide systematic exploration of DNN’s internal logic. Input images are modified by several domain-specific transformations, and a transformed image is selected for inclusion into a test suite if it fools at least one of several similarly trained DNNs. Their study finds that NC is a better metric than code coverage and increasing NC tends to increase $\ell_1$-distance among inputs.

DeepTest [49] is a gray-box, NC-guided test suite generation approach using metamorphic relations. This effort introduced a wider range of affine transformations to predict the steering angle of an autonomous vehicle. DeepRoad [53] is a GAN-based metamorphic testing approach that utilizes a shared latent space representation to perform a sophisticated style transfer of some target road condition, i.e., rain, snow, etc., to a given source image. DeepRoad makes no attempt to systematically explore the possible input space via a metric like NC but finds that GAN-based transformations could expose new faulty behaviors.

DeepGauge expands on the idea of NC [32] by introducing three new neuron-level coverage criteria and two layer-level coverage criteria to produce a multi-granular set of DNN coverage metrics. To argue for the utility of these metrics, DeepGauge’s evaluation
uses standard adversarial attack techniques [7, 13, 28, 39] to generate test suites. It then compares the NC of the original test suite against that of the new, augmented test suite, boosted by the generated adversarial examples. By doing so, it finds some evidence that adding adversarial examples tends to increase NC in terms of most of the proposed criteria. In Section 5, we report our results that explicit effort to increase NC actually does not improve defect detection and is often harmful in terms of naturalness and output impartiality.

Recent on-going work [10, 31] found some preliminary evidence that the correlation between NC and DNN robustness is rather limited and that structural coverage for DNNs could be misleading. Specifically, their test suites are generated using the standard adversarial attack methods, and their evaluation is limited to defect detection only. Our study scope is more comprehensive: we use automated, quantitative measures of naturalness and output impartiality in addition to defect detection and systematically investigate the trade-offs; we design a novel diversity promoting regularizer to extend existing adversarial attack algorithms; and we include both classification models and regression models (8 models in total), as opposed to classification models only.

It is worth noting that our proposed output impartiality criteria discussed in Section 4.3 is different from the concept of fairness in machine learning [8]. More specifically, fairness in ML is concerned with the bias of an ML model with respect to sensitive attributes, such as gender or race. Along a similar vein, Themis, a software fairness testing tool by Galhotra et al. [11], automatically detects causal discrimination between input-output pairs for user-specified attributes. In sharp contrast with these notions of fairness, our output impartiality is a measure of the bias of a test suite with respect to the exercise of diverse output behaviors in an ML model.

Adversarial Attacks. Recent studies show that DNNs are vulnerable to adversarial examples [13, 48], i.e., by adding a very small, often visually imperceptible, perturbation to an input, a well-trained DNN may produce misclassifications. While adversarial attacks employ a variety of methods to induce erroneous behavior, their effectiveness is largely measured by the attack success rate of the perturbed inputs and its distortion from the original inputs. Most optimization-based adversarial attacks [7, 33] are based on $\ell_2$ or $\ell_\infty$ norm-based perturbation. Some work [40, 49] has attempted to improve or side step the norm constraint with certain domain specific transformations. In our evaluation of neuron coverage, we use the standard attack methods with $\ell_\infty$ norm constraint, because these methods are efficient and can generate more natural examples.

Adversarial attack algorithms offer both targeted and untargeted attacks for perturbing inputs to be predicted as some other class. Untargeted attacks aim to turn the prediction into any incorrect class, while targeted attacks aim to turn the prediction into a specific class. We exclusively use untargeted attacks to give them more freedom to perturb the input in whichever way NC maximization incentivizes.

3 STUDY METHODS

This section describes the datasets, DNN models, and adversarial attack algorithms used for our empirical study and describes our diversity promoting regularizer to increase neuron coverage.

3.1 Datasets and DNNs

Table 1 summarizes architectural details of all the DNNs under test. CIFAR10 [25] is a dataset containing 32x32x3 RGB pixel images representing ten mutually exclusive classes of naturally occurring entities that are suitable for IS and FID realism measurement. We use two well-known pre-trained DNNs: a 56-layer ResNet [15, 19] and a 121-layer DenseNet [18, 41], both of which achieve competitive performance on this dataset.

MNIST [30] is a large, well-studied dataset containing 28x28x1 gray-scale pixel images representing handwritten digits from 0 to 9. For this dataset, we consider two fully connected neural networks: FCNet5 with 5 hidden layers and FCNet10 with 10 hidden layers, and two convolutional neural networks: Conv1DNet and Conv2DNet. Both of the convolutional neural networks have 2 convolutional layers followed by 2 fully connected layers, but vary the primary convolutional layer type from 1D to 2D. All MNIST DNNs were trained for 10 epochs using an Adam optimizer [24].

The two realism metrics we employ—IS [43] and FID [16]—are tuned on the internal structures of natural images which generally have both foregrounds and backgrounds. Because such naturalism is not applicable to a digit recognition task, we exclude MNIST when studying the relationship between NC and naturalness.

Udacity Self-Driving Car [1] is a dataset containing 480x640x3 RGB pixel images extracted from video footage shot by a camera mounted to the front of a moving vehicle and the corresponding angle of the steering wheel ($\pm 25^\circ$) for each frame. We use two pre-trained DNNs: DAVE2 and DAVE2-Norminit (abbreviated DAVE2-N), which are used by DeepXplore [40] and originally designed by NVIDIA [5].

3.2 Measuring Neuron Coverage

Pei et al. [40] formally define neuron coverage by the following:

$$\text{neuron}_{\text{cov}}(T, x, t) = \frac{|\{n\forall x \in T, |\text{out}(n, x) > t\}|}{|N|}$$

where $N = \{n_1, n_2, \ldots\}$ represents all the neurons in the DNN; $T = \{x_1, x_2, \ldots\}$ represents all test inputs (i.e., those to be perturbed); $\text{out}(n, x)$ is a function that returns the output value of neuron $n$ for
a given test input $x$ which is scaled to be between 0 and 1 based on the minimum and maximum neuron activations for the layer; and $t$ is the user-set threshold for determining whether a neuron is sufficiently activated.

Figure 1 depicts an example neural network with a single hidden layer. Each circular node corresponds to a neuron organized and color-coded by layer. The hidden layer neurons also contain their layer-wise scaled activations in parentheses for comparison against a NC threshold. $\theta$ represents an output layer of 1 neuron (i.e., class logits, probabilities, etc.).

Figure 1: Single Layer DNN. $\mathbb{1}$ represents inputs (i.e., pixels, features, etc.). $\mathbb{2}$ represents a hidden layer of 5 neurons, where parentheses denote activations scaled between 0 and 1 for comparison against a NC threshold. $\mathbb{3}$ represents an output layer of 1 neuron (i.e., class logit, probability, etc.).

### 3.3 Adversarial Attack Algorithms

Using adversarial attacks for test generation is analogous to fuzzing in traditional software testing and acts as a means of introducing targeted perturbations. We select the following two adversarial attack algorithms $[7, 33]$ due to their widespread usage in the ML literature.

**Carlini-Wagner (CW) $[7]$** constructs the adversarial example $x + \delta$, where $x$ is the original input to attack, $\delta$ is the adversarial perturbation, by solving the following optimization problem:

$$\min_{\delta} \alpha \cdot L(h(x + \delta), y) + \|\delta\|_p \quad \text{subject to} \quad x + \delta \in [0, 1]^n,$$

where $y$ is the label of $x$, $L$ is a suitable loss function, $h$ is the target model, $\|\cdot\|_p$ denotes the $\ell_p$-norm such as $\ell_\infty, \ell_0, \ell_2$ norms, and $\alpha$ is a scaling constant to balance the loss $L$ and the $\ell_p$-norm. The intuition behind the CW attack is to find some small perturbation $\delta$ that we can add to the original input $x$ such that it will lead the target model to change its classification. To achieve this, the CW attack exploits the loss function $L$ to guide the generation of $\delta$ that will make the target model’s classification on $x + \delta$ different from $x$. In addition, by minimizing the $\ell_p$-norm of $\delta$, the CW attack can ensure that such perturbation is small. In this effort, we use the $\ell_\infty$ norm, where distance is measured by the pixel with the greatest magnitude change from its original value. For the loss function $L$, we use the loss function provided by Carlini and Wagner $[7]$ for our classification tasks. For our regression models, we substitute the standard CW loss function for a custom loss designed for regression tasks by Meng et al. $[35]$.

**Projected Gradient Descent (PGD) $[33]$** finds the adversarial example $x + \delta$ by solving the following maximization problem:

$$\max_{\delta} L(h(x + \delta), y) \quad \text{subject to} \quad \|\delta\|_p \leq \epsilon,$$

where $y$ is the label of $x$, $h$ represents the target model, $L$ is the loss function for training $h$, $\epsilon$ is the perturbation limit. The maximization step will guide us to find the adversarial example and the $\ell_p$ norm constraint will make the perturbation small. For the PGD attack, projected gradient descent is performed to solve the above constrained optimization problem. In our implementation, we consider the $\ell_\infty$ norm constraint as in the CW attack, and use the sign of the gradient $[13]$ to efficiently solve the maximization problem. In addition, for the loss function $L$, we choose the cross-entropy loss for classification tasks and mean square error for regression tasks. We vary a different perturbation limit $\epsilon \in \{0.1, 0.2, 0.3\}$ for the norm bounds to explore its possible effects on NC.

### 3.4 Extending Attacks to Increase NC

Adversarial attacks aim at creating perturbed inputs to achieve two primary objectives — maximizing loss while keeping $\ell_p$-norm distance from the original inputs small. Previous research $[32, 40]$ found that these algorithms do not produce any significant variation in NC. In order to increase NC while leveraging the skeleton of existing adversarial attacks, we design a novel adversarial attack regularizer to incorporate the maximization of NC as an additional objective. Our regularizer works by penalizing skewed layer-wise activations and thus promotes more diverse neural activation distributions. The promotion of diversity has the effect gravitating all neurons toward the average magnitude of activation. Here we show the extended CW attack, augmented with our new diversity-promoting regularizer:

$$\min_{\delta} \alpha \cdot L(h(x + \delta), y) + \|\delta\|_p + \lambda \cdot \sum_l \text{div}(\text{out}_l(x + \delta), U) \quad \text{subject to} \quad x + \delta \in [0, 1]^n,$$

where $\lambda > 0$ is a user-set diversity weight to control how strongly we wish to induce higher NC; $\text{div}()$ is a divergence function; $\text{out}_l()$ is a function that returns the neural activations from the $l^{th}$ layer of the DNN for the perturbed inputs $x + \delta$; $U$ represents a uniform distribution; and we consider $\ell_\infty$ norm in our method (i.e., choosing $p = \infty$). We use the Kullback-Leibler (KL) divergence $[27]$ to implement our $\text{div}()$ function, but any other measure of the distance between two probability distributions could be suitable. KL divergence measures how much information is lost by approximating the neural activations as if they were perfectly uniform — the higher the loss, the less diverse the activations. With a sufficiently high regularization weight placed on this objective, diversity promotion can induce previously inactive neurons to fire and thereby increase NC. We use a logarithmic scale to explore the effect of the diversity regularization weight, $\lambda \in \{10^0, 10^1, 10^2, 10^3, 10^4, 10^5\}$.

Figure 2 shows how our regularization promotes higher NC by having more neurons activated by visualizing neuron activation at a given layer in Conv2DNet.
We adopt a standardized delineation of correlative significance $k \in \{t_1, \ldots, 0.2\}$.

Table 2 shows our regularizer’s effectiveness in terms of the average and maximum percent increases in NC over the baseline NC of the original test suite images for all models. Naturally, already highly activated DNNs are more difficult to activate further, making the NC at $t = 0.5$ undesirable for comparison purposes. On the other hand, NC at $t = 0.0$ and NC at $t = 0.25$ activate significantly smaller portions of the network. Therefore, we report primarily on the NC at $t = 0.2$ for presenting visual figures.

As an implementation note, our diversity-promoting regularizer can target a specific layer, contiguous and non-contiguous layer subsets, or all layers simultaneously. In our experiments, we vary the target layer one at a time, primarily to evaluate the sensitivity of NC to this regularization. For the MNIST models, we target each layer in turn. However, for larger models, we target $k$ layers (default $k = 6$) evenly spaced in the model, starting from the first hidden layer and ending at the output layer.

4 FINDINGS

For each configuration, we use an adversarial attack algorithm to generate a DL test suite and then assess NC at the threshold $t = 0.2$. For each dataset, we randomly select one hundred input images for adversarial perturbation such that every class is equally represented. This is to ensure that the images selected for perturbation have output impartiality before perturbation. We then perform a correlation analysis of 2,095 test suites to measure the strength, direction, and significance of the relationship between NC and our three test criteria.

All correlations are presented in a tabular form and we visualize a sample of the NC at $t = 0.2$ results for PGD for presentation purposes. We adopt a standardized delineation of correlative significance laid out by Ratner [42] to characterize values between 0 and $\pm 0.3$ as weak, $\pm 0.3$ to $\pm 0.7$ as moderate, and $\pm 0.7$ to $\pm 1.0$ as strong. Correlation coefficients are also color-coded according to whether or not they are statistically significant. Gray indicates a p-value $> 0.05$ and such values are discounted in our subsequent analysis. **Emboldened** values indicate that the results support the associated hypothesis and all others do not.

Figure 2: Neural Activation Before and After Regularization: our regularizer significantly promotes NC at the threshold $t = 0.2$.

4.1 Defect Detection

4.1.1 Study Method. Since our approach relies on adversarial attacks to generate test suites, we equate the attack success rate (ASR) with defect detection rate (DDR) and use both measures interchangeably. Let $\text{pert\_acc}$ represent the classification accuracy on the adversarially perturbed suite of test inputs ($T$), then DDR is simply $\text{ASR}(T) = 1 - \text{pert\_acc}$. In order to use the same metric for the regression driving models, we discretize their continuous outputs into 25 equal-width intervals [50], each representing a $2^\circ$ difference in steering angle.

4.1.2 Results.

Figure 3 visualizes the relationship between NC and ASR, broken down by DNN for the PGD attack, which shows that NC is volatile and NC does not consistently correlate with defect detection. Even for models that share a large degree of architectural similarity, like the FCNet5 and FCNet10 models, the correlations differ in both strength and direction, reinforcing the unpredictability of NC.

Table 4 shows the results of all configurations broken down by an attack algorithm, network, and $t$ threshold. Only 2 out of 64 correlations satisfy the hypothesis that NC is both positively and strongly correlated with defect detection. Independent of direction, 58% of experimental configurations show a weak correlation, while 25% are merely moderate. The correlation is positive in only 36% of configurations, negative in 52%, and non-existent in 12%.

Table 3: Experimental Variables

Figure 4 depicts the relationship between NC and IS and FID, broken down by metric, model for the PGD attack. Once again, the wide fluctuation of strongly negative and strongly positive correlations underscores the volatility of NC. Table 5 shows the results for each attack algorithm, model, and t threshold. Only 1 out of 64 correlations satisfy the hypothesis that NC is both positively and strongly correlated with improving input naturalness. Independent of direction, 38% of configurations show a weak correlation while another 45% are merely moderate. Independent of strength, the correlation is positive in only 31% of cases.

Unlike the mixed results for IS, increasing NC invariably increases FID, making the inputs less natural. In fact, not a single configuration in the FID experiment supports the hypothesis.

More than half of the PGD results across both IS and FID are statistically insignificant. This is because PGD attacks enforce a more strict ε perturbation limit, while the perturbations of CW attacks are theoretically unbounded and thus minimize the distortion as much as possible. Since this limit tightly constrains the range of measurements, it is difficult to assess the correlation with NC.

Figures 5 and 6 show a sample of two test suites with a 14% NC difference. While both sets of images are noticeably distorted, test suite # 140 is clearly more unnatural. Test suite # 33 has an IS about 33% higher and an FID about 29x smaller, both confirming the intuition that Figure 5 with NC = 0.29 is more natural than computing the Fréchet distance between two Gaussians fitted to feature representations of the final average pooling layer within the InceptionV3 network [47]. The inventors, Heusel et al., find evidence that FID captures the similarities of generated images better than IS and that FID correlates well with human judgement of visual quality. Unlike IS, the lower the FID value, the more realistic the images are, since the distance from the original images is smaller. Therefore, we investigate whether NC has a strong negative correlation with FID.

We exclude MNIST from the measurement of IS and FID, since it is inapplicable to discuss naturalness of highly, pre-processed MNIST digit recognition and IS and FID use InceptionV3 network, which is trained to recognize ImageNet classes [9]. Therefore, we use only CIFAR10 and driving datasets for examining the relationship between NC and naturalness.

4.2 Naturalness

DL systems are designed to solve real-world problems and therefore a test suite must have realistic and natural inputs. We investigate whether maximizing NC can generate test suites reflecting the naturalness of the expected input space.

4.2.1 Study Method. Appraising the visual quality of an image is highly subjective and there is still no definitive solution on how to formalize its naturalness. Fortunately, research into generative adversarial networks (GANs) [12] has produced several popular metrics for this purpose. We select the two most highly cited metrics from the GAN literature to objectively measure naturalness.

The Inception Score (IS) [4, 43] formalizes the concept of naturalness by decomposing it into the following two sub-concepts:

- **Salience**. Of the possible class labels that could be applied to an individual image, only one has a high probability and the others are very low. This corresponds to the image being highly recognizable.
- **Diversity**. There are many different kinds of classes present across all images in the set.

The Fréchet Inception Distance (FID) [16, 36] is a measure of similarity between two datasets of images. It is calculated by computing the Fréchet distance between two Gaussians fitted to feature representations of the final average pooling layer within the InceptionV3 network [47]. The inventors, Heusel et al., find evidence that FID captures the similarities of generated images better than IS and that FID correlates well with human judgement of visual quality. Unlike IS, the lower the FID value, the more realistic the images are, since the distance from the original images is smaller. Therefore, we investigate whether NC has a strong negative correlation with FID.

We exclude MNIST from the measurement of IS and FID, since it is inapplicable to discuss naturalness of highly, pre-processed MNIST digit recognition and IS and FID use InceptionV3 network, which is trained to recognize ImageNet classes [9]. Therefore, we use only CIFAR10 and driving datasets for examining the relationship between NC and naturalness.

4.2.2 Results. Figure 4 depicts the relationship between NC and IS and FID, broken down by metric, model for the PGD attack. Once again, the wide fluctuation of strongly negative and strongly positive correlations underscores the volatility of NC. Table 5 shows the results for each attack algorithm, model, and t threshold. Only 1 out of 64 correlations satisfy the hypothesis that NC is both positively and strongly correlated with improving input naturalness. Independent of direction, 38% of configurations show a weak correlation while another 45% are merely moderate. Independent of strength, the correlation is positive in only 31% of cases.

Unlike the mixed results for IS, increasing NC invariably increases FID, making the inputs less natural. In fact, not a single configuration in the FID experiment supports the hypothesis.

More than half of the PGD results across both IS and FID are statistically insignificant. This is because PGD attacks enforce a more strict ε perturbation limit, while the perturbations of CW attacks are theoretically unbounded and thus minimize the distortion as much as possible. Since this limit tightly constrains the range of measurements, it is difficult to assess the correlation with NC.

Figures 5 and 6 show a sample of two test suites with a 14% NC difference. While both sets of images are noticeably distorted, test suite # 140 is clearly more unnatural. Test suite # 33 has an IS about 33% higher and an FID about 29x smaller, both confirming the intuition that Figure 5 with NC = 0.29 is more natural than computing the Fréchet distance between two Gaussians fitted to feature representations of the final average pooling layer within the InceptionV3 network [47]. The inventors, Heusel et al., find evidence that FID captures the similarities of generated images better than IS and that FID correlates well with human judgement of visual quality. Unlike IS, the lower the FID value, the more realistic the images are, since the distance from the original images is smaller. Therefore, we investigate whether NC has a strong negative correlation with FID.

We exclude MNIST from the measurement of IS and FID, since it is inapplicable to discuss naturalness of highly, pre-processed MNIST digit recognition and IS and FID use InceptionV3 network, which is trained to recognize ImageNet classes [9]. Therefore, we use only CIFAR10 and driving datasets for examining the relationship between NC and naturalness.

Defect Detection. Our findings reject the hypothesis that NC is strongly and positively correlated with defect detection. Only 3% of the configurations supported this.

Table 5: Correlation between NC & Naturalness: Gray indicates a p-value > 0.05

Figure 4: NC_{t=0.2} vs Naturalness (IS / FID): the results show both strongly negative and strongly positive correlations.

Figure 6 with NC = 0.33. Here, increasing NC makes noisier and more noticeably perturbed inputs, thus a less valuable test suite.

4.3 Output Impartiality

Figure 5: Test Suite #33. NC_{t=0.2}: 0.29 - IS: 1.97 - FID: 0.10

Figure 6: Test Suite #140. NC_{t=0.2}: 0.33 - IS: 1.48 - FID: 2.96

Naturalness. Only 3% of all experimental results supported the hypothesis that NC is strongly and positively correlated with naturalness. 56% of the test suites are actually negatively correlated, implying that maximizing neuron coverage is likely to undermine naturalness.

The final dimension of our investigation probes the relationship between NC and the bias in model predictions. This idea of measuring the impartiality of model predictions is motivated by the output-uniqueness test selection criteria [2] in traditional software.
testing, which argues that a test suite must exercise diverse output behavior and should not prefer only a few output values. Investigating the relationship between NC and output impartiality is also motivated by several observations about DNN behavior by prior work. Ilyas et al. [20] found that adversarial examples can be created by incorporating unnoticeable features of other classes to confuse the DL model. Similarly, Pei et al. found that different classes are associated with distinctive neuron activation patterns [40].

Consider a balanced test suite comprised of inputs evenly drawn from multiple classes. Suppose that the test suite is fed to a model and the model predicts always the same class label. This indicates output skew. Since one important aspect of testing is to exercise as much diverse output behavior as possible, we investigate the relationship between NC and the impartiality of predicted outcomes.

4.3.1 Study Method. We characterize output impartiality based on the distribution of class predictions while keeping the input distribution uniform (i.e. the test suite contains an equal number of inputs from each class). A test suite with the highest output bias (or the lowest impartiality) reflects that all inputs are predicted to belong to only one class. We use Shannon Entropy [45] to assess the skew of the output class distribution. A high entropy score entails high impartiality (low bias), while a low entropy entails high bias. We normalize the entropy to be on a scale between a low of 0 and a high of 1 by dividing each test suite by the maximum entropy possible given the total number of classes. Thus, we formally define an output impartiality metric for a test suite $T$ with $|C|$ possible classes, indexed by $k$ - below:

$$output\_impartiality(T) = \frac{\sum_{t \in C_k} P_{t \in C_k} \log P_{t \in C_k}}{\log |C|},$$

where $|C|$ is the cardinality of classes and $P_{t \in C_k}$ represents the percentage of the test cases $t$ predicted to belong to class $C_k$. For the regression models, we use the same discretization method as before to enable the use of this metric.

4.3.2 Results.

Figure 7 visualizes the relationship between NC and output impartiality by DNN for CW. The results show that increasing NC creates bias in output behavior. Table 6 shows the results of all configurations by an attack algorithm and $t$ threshold. Only 3 out of 64 configurations show that NC is both positively and strongly correlated with output impartiality. Independent of strength, the correlation is negative in 33% of correlations. Independent of direction, 62% of experimental configurations show a weak correlation while 32% are moderate.

4.3.3 Investigating Output Bias Caused by NC. In addition to the previous section’s correlation analysis, we design another experiment to investigate which classes are likely to be over-represented in the outputs after a test suite has been perturbed to maximize NC.

The idea of maximizing NC during test suite generation does not take into account that different classes of inputs can already have different baseline NC levels. For example, it may be the case that a set of inputs containing only the “dog” class in CIFAR10 has a NC$_{t=0}$ = 0.9 while another set of inputs containing the same number of “cars” has a NC$_{t=0}$ = 0.6. Increasing NC may then bias the perturbations—and therefore the output predictions—towards the class “car” with the higher NC baseline instead of “dog”. Below we describe an experiment conducted with the MNIST dataset to investigate this further.

We generate 10 partitions of the test data—one partition for each class—by randomly selecting 100 instances of that class from the test set. These partitions are then used to calculate a class-specific NC baseline. Since NC depends on the choice of $t$, we repeat NC baseline calculation for each class label, while varying $t$ from 0 to 0.9 in an increment of 0.1. This process reveals which class label has the highest NC baseline, the second highest NC baseline, and so on. In other words, we rank class labels from the highest NC (Rank 1) to the lowest NC (Rank 10).

Suppose that class label 8 has a rank $\{1, 3, 3\}$ and class label 1 has a rank $\{8, 9, 10\}$, respectively for $t \in \{0, 0.5, 0.9\}$. A low average rank for class 8 (2.3) indicates that class 8 tends to have a high NC baseline regardless of $t$. On the other hand, a high average rank for class 1 (9) indicates that class 1 tends to have a low NC baseline. Therefore, during NC maximization, the perturbation process may favor over-representing class 8 in the output predictions. However, suppose that class 3 has an average ranking closer to 5—the midpoint of 10 possible labels. That implies that class 3 may have a high NC baseline under a certain threshold, but may have a low NC baseline under another threshold, or places the fifth for all $t$, etc. Thus, it would be unlikely for NC maximization to consistently prefer over-representation of outputs associated with class label 3 in the resulting test suite.

Concretely, an average rank closer to 1 indicates a greater likelihood of being over-represented in the output distribution through NC-maximization. Table 7 reports the average class ranks for the 10 class labels of MNIST. Here, we can see that class label 8 tends
Is Neuron Coverage a Meaningful Measure for Testing Deep Neural Networks?

5 DISCUSSION

5.1 Comparison with DeepXplore

We conduct the same three-part correlation analysis on DeepXplore’s results to see whether similar trade-offs exist in the test suite generated by another technique that uses NC maximization as a guidance criteria. We apply the publicly available implementation of Pei et al’s DeepXplore [40] to the MNIST and Driving datasets and generate test suites. In these test suites, surprisingly not a single correlation is sufficiently strong enough to support the three hypotheses that NC is positively related with defect detection, naturalness, and output impartiality. This result suggests that the consequences of NC maximization are not dependent on a particular test generation technique, but are rather an essential limitation of NC as a testing adequacy criteria.

5.2 How Meaningful is a Neuron?

The viability of NC as a DNN testing metric is underpinned by the idea that “each neuron independently extracts a specific input feature” [40] rather than collaborating with other neurons. However, recent research into DNN visualization techniques [37, 38, 51] has demonstrated that this is not so—neuron independence and local feature extraction do not accurately characterize DNN behavior. Instead, the neurons in a layer interact with one another to pass information to subsequent layers and NC does not capture the richness of such neuron interactions. While the probability that a neuron distinctly encodes a specific feature increases the deeper it is situated in the DNN, many of the neurons represent an amalgam of very different abstract concepts, like the visualization of pixels leading to high activations of certain neurons in Figure 9 [38]. This observation raises serious doubts about whether neurons are even
the right semantic units for understanding DNN behavior, further questioning the viability of NC as a meaningful test metric.

We therefore advocate incorporating other test objectives such as naturalness and output impartiality and use multi-objective search techniques for testing DL systems. Our experience of adapting existing adversarial attack algorithms for test generation has shown that it is fairly easy to create inputs that lead to misprediction by sacrificing naturalness, and that it is also fairly easy to perturb a test suite to produce a high NC score by skewing the output distribution. Our results call for more research on how to generate realistic inputs that reveal meaningful undesired behavior of DL systems. Such research direction may necessitate new means to enable users to easily specify domain specific constraints expressively and to leverage those constraints to guide test generation.

Per open science policy, the code and data is available at: https://doi.org/10.5281/zenodo.3698556.

## 6 CONCLUSION

Recent effort to test deep learning systems has produced an intuitive testing adequacy metric, called neuron coverage and its several variants. Prior work has also produced several test generation techniques that use NC as a guidance criteria and some has found evidence that adding adversarial inputs to an existing test suite to produce a high NC score by skewing the output distribution. Subsequently, such limited focus on NC could easily produce a test suite that does not cover other interesting portions of the potential input space.
