Abstract. These two rule-oriented paradigms of databases have been the focus of extensive research and are now coming of age in the commercial DBMS world. However, the systems developed so far support well only one of the two paradigms—thus limiting the effectiveness of such systems in many applications that require complete integration of both kinds of rules. In this paper, we discuss the technical problems that make such an integration difficult, and trace their roots to a lack of a unified underlying semantics. Then, we review recent advances in the semantics of non-monotonic logic and show that they can be used to unify the foundations of active databases and deductive databases. Finally, we outline the design a new rule language for databases that integrates a deductive system with a trigger-based DBMS.

1 Introduction

Rules provide the main paradigm for expressing computation in active databases and deductive databases. Yet, there has been little formal work on the unification of these powerful paradigms, although there are many important applications that could benefit from such a marriage. While cultural and historical biases might also have had a role in this chasm, the root of the problem is actually technical and can be traced to certain semantic inadequacies in both approaches.

Several active database languages and systems have been proposed so far: a very incomplete list include [3, 5, 9, 19, 20, 29]. However, there is no unifying semantic theory for active databases: most of the work done so far has concentrated on explaining operational semantics of particular systems. On the contrary, deductive databases are endowed with extraordinarily rich semantic foundations: not one but three equivalent formal semantics exist for Horn clauses that form the core of deductive database languages [30, 17]. Unfortunately, this elegant semantics is brittle and can not be generalized easily to deal with non-monotonic constructs, such as negation and updates. Similar non-monotonic reasoning problems have emerged in the areas of knowledge representation and of logic programming, and remain the focus of intense research as

many difficult problems remain open. While deductive databases encountered early successes in this area (e.g., with the introduction of the concept of stratified negation), recent progress has been very slow. No totally satisfactory semantics currently exist for programs which use non-monotonic constructs such as negation and aggregates in recursion—and the problem of updates in recursion is understood even less.

Given this rather ominous background, the solution presented in this paper is surprisingly simple and general. We introduce the notion of XY-stratified programs that allow non-monotonic constructs in recursive rules. Then, we show that a formal semantics for updates and triggers in databases can be given using XY-stratified programs. The blueprints for the design of a unified rule language for active databases and deductive databases follow from such a solution.

2 Non-Monotonic Constructs

The area of non-monotonic reasoning has benefited significantly from research in deductive databases. The adoption of the fixpoint-based bottom-up approach to define the declarative and constructive semantics of logic programs lead almost immediately to the concept of stratified negation and stratified set aggregates [23]. This concept removes several of the limitations and problems of Prolog’s negation-by-failure, and it is conducive to efficient implementation, as demonstrated by systems such as *Glue-Nail*, *LDL* and *CORAL* [22, 6, 26]. However, experience gained with real-life applications [28] revealed that stratification is too restrictive and there remain many important applications where negation and set aggregates are needed: such applications, range from processing a Bill of Materials to finding the shortest path in a graph [34].

Therefore, during the last five years, a substantial research effort has been devoted to solving the non-stratification issue. This endeavor has produced significant progress on the theoretical front, with the introduction of concepts such as locally stratified programs, well-founded models [13], and the stable models [10], but it has not yet begotten a solution that is both general and practical. Indeed a practical solution must satisfy three difficult requirements, inasmuch as it must

- have a formal logic-based semantics,
- have a simple and intuitive constructive semantics,
- be amenable to efficient implementation.

Thus, in addition to requiring formal semantics and efficient implementation, any practical proposal must also stress the importance of having a simple concrete semantics: i.e., one that can be easily comprehended by the application programmer, without a need to understand abstract formalisms. For instance, a notion such as stratification can be mastered by a programmer, who can make full use of it without having to understand its formal perfect-model semantics. Furthermore, it is simple for a compiler to verify that stratification is satisfied, and then support stratified programs by an efficient bottom-up computation. However, an understanding of the logical formalism is required to understand notions such as well-founded models or stable models.

Furthermore, no simple syntactic check exists for deciding whether a program has a well-founded model or a stable model; when such models exist their computation can be very expensive.

The notion of XY-stratified programs was recently proposed to overcome these difficulties [35]. This is a special subclass of locally stratified programs that is easy for a compiler to recognize and implement using the fixpoint-based computation of deductive DBs. It was shown in [35] that classical computational problems such as Floyd’s shortest path algorithms, can be expressed naturally by programs in this class using non-stratified negation and aggregates. In this paper, we will build on such a semantics to provide a formal model of updates in deductive databases and triggers in active databases.

The problem of providing a formal semantics to updates in the context of logic also represents a difficult challenge. Several of the approaches proposed deal with the more general problem of modeling revisions of knowledge bases—i.e., including additions, deletions and modifications of rules [4, 7, 33, 14]. As a result, these theories are more complex and less conducive to efficiency than it is desirable in a practical semantics, according to the criteria discussed above. Therefore, we will restrict our attention to the problem of modifying the extensional database only [21]. Most of the work done in this more specific context is based on Dynamic Logic [8]. In particular, the approach given in [31, 18] uses dynamic logic to formalize a concrete semantics where the updates take place according to rule instances—a *tuple-at-a-time* semantics often leading to non-determinism. However, relational databases support a *set-at-a-time* update semantics, where all the applicable updates are fired at once, in parallel. A set-at-a-time semantics based on dynamic logic was adopted and efficiently implemented in *LDL* [25, 6]. While the *LDL* design has progressed further than other systems toward a complete integration of database-oriented updates into a logic-based language, several problems remain, such as multiple update rules sharing the same heads, and failing goals after update goals [16]. Furthermore, since dynamic logic is quite different from standard logic, the two do not mix well, and, as a result, updates are not allowed in recursive *LDL* rules; a special construct, called **forever** had to be introduced to express **do-while** iterations over updates [25]. A further illustration of the difficulties encountered by declarative logic-based languages in dealing with updates is provided by the design of the *Glue-Nail* system [22]. In this second-generation deductive database system, updates were banned from the core declarative language and relegated to the procedural shell that is tightly wrapped around the core [26].

Viewed against the tormented landscape of previous work, the model of updates and active databases proposed in this paper is surprisingly simple. Basically, we define rules with updates in their heads by simply re-writing them into equivalent update-free logic programs that are XY-stratified. The common semantics of active and deductive predicates, so obtained, is the basis for our unification of the active and deductive aspects of databases. This semantics is conducive to the design of a powerful language capable of expressing reasoning, triggers and detection of events as required by the next generation of intelligent database applications.

2.1 XY-Stratification

We begin with a simple example ¹ that computes the nodes X of a graph g reachable from a given node a , and the minimum distance of X from this node:

Example 1 *Reachable nodes:*

$$\begin{aligned} r_0 &: \text{delta}(\text{nil}, X, 1) \leftarrow g(a, X). \\ r_1 &: \text{delta}(s(I), Y, D1) \leftarrow \text{delta}(I, X, D), g(X, Y), \\ &\quad \neg \text{all}(I, Y, -), D1 = D + 1. \\ r_2 &: \text{all}(s(I), Y, D) \leftarrow \text{all}(I, Y, D), \text{delta}(s(I), -, -). \\ r_3 &: \text{all}(I, Y, D) \leftarrow \text{delta}(I, Y, D). \end{aligned}$$

This program presents several unusual traits. A most obvious one is the presence of terms such as `nil`, `I`, `s(I)` in the first argument of the recursive predicates. These arguments will be called *stage arguments*, and their usage is for counting as in the recursive definition of integers: `nil` stands for zero and `s(I)` stands for `I+1`.

The intuitive meaning of the program of Example 11 is quite obvious: it implements a seminaive computation of a transitive closure [25], through the use of two predicates: `delta` contains the new values, and `all` is the union of all values computed so far. In rule r_1 , `all` is used for checking that no previous (therefore shorter) path exists to this node.

The formal semantics of the program also supports its intuitive semantics. Because of its particular syntactic form, the program is locally stratified, where each stratum corresponds to a different value of the stage argument. The first stratum contains atoms of the form:

$$\text{delta}(\text{nil}, \dots), \text{all}(\text{nil}, \dots)$$

the next stratum consists of all atoms of the form:

$$\text{delta}(s(\text{nil}), \dots), \text{all}(s(\text{nil}), \dots)$$

and so on. As we shall see later, this particular syntactic form of the recursive rules, w.r.t. the stage arguments, makes it simple for a compiler to detect the occurrence of such a locally stratified program. Furthermore, this type of program can be implemented efficiently using a modified fixpoint computation.

It is well-known that the perfect model of such a program is characterized by a transfinite computation called iterated fixpoint [23]. This proceeds as follows: the least fixpoint is first computed for the first (bottom) stratum; then, once the least fixpoint is computed for the n -th stratum, the least fixpoint is computed for the $n + 1$ -th stratum. The transfinite computation of perfect models simplifies dramatically for the program

¹We assume our reader familiar with the basic concepts pertaining to Datalog and logic rules, including the concept of locally stratified programs and the *iterated fixpoint procedure* that computes the perfect model of these programs [23, 25]. Given a program P , a set of rules of P defining a maximal set of mutually recursive predicates will be called a *recursive clique* of P .

at hand. Assume, for now, that the stratification is determined by the values of stage arguments. The fixpoint at the bottom stratum is reached after firing rule r_0 followed by r_3 . The fixpoint for the stratum $\mathbf{s}(\mathbf{nil})$ is reached by firing rule r_1 , followed by firing r_2 and r_3 . Then, the higher strata are inductively generated by firing these three rules in the same order. Therefore, the general transfinite procedure to compute perfect models here reduces to the customary fixpoint iteration. Moreover, various improvements can be made to this fixpoint computation to ensure that it executes efficiently. In fact, while rule r_2 seems to suggest that a complete copying of the old relation is needed at each step, no such operation is needed in reality. In fact, the only instances of rules that can produce new atoms are those instantiated with stage values from the current stratum: values from the old strata are not used and can be discarded. Thus, if we keep the values of the stage variable in a separate memory cell, all is needed to perform the copy operation is to increase the value of the integer in this cell by one.

Given a recursive clique, Q , the first arguments of recursive predicates of a rule r (of Q) will be called the *stage arguments* of r (of Q) ² Then a recursive rule is either an

- **X-rule** if all the stage arguments of r are equal to a simple variable, say J , which does not appear anywhere else in r , or an
- **Y-rule** if (i) some positive goal of r has as stage argument a simple variable J , (ii) the head of r has stage argument $s(J)$, (iii) all the remaining stage arguments are either J or $s(J)$ and (iv) J does not appear anywhere else in r .

In Example 11, r_3 is an X-rule, while r_1 and r_2 are Y-rules. A recursive clique Q such that all its recursive rules are either X-rules or Y-rules, will be said to be a recursive *XY-clique*.

Priming: $p'(\dots)$ will be called the primed version of an atom $p(\dots)$. Given an XY-clique, Q , its primed version Q' , is constructed by priming certain occurrences of recursive predicates in recursive rules as follows:

- X-rules: all occurrences of recursive predicates are primed,
- Y-rules: the head predicate is primed, and so is every goal with stage argument equal to that of the head.

The primed version of our example is as follows:

$$\begin{aligned}
r_0 &: \mathbf{delta}(\mathbf{nil}, \mathbf{X}, 1) \leftarrow \mathbf{g}(\mathbf{a}, \mathbf{X}). \\
r_1 &: \mathbf{delta}'(\mathbf{s}(\mathbf{I}), \mathbf{Y}, \mathbf{D1}) \leftarrow \mathbf{delta}(\mathbf{I}, \mathbf{X}, \mathbf{D}), \mathbf{g}(\mathbf{X}, \mathbf{Y}), \\
&\quad \neg \mathbf{all}(\mathbf{I}, \mathbf{Y}, _), \mathbf{D1} = \mathbf{D} + 1. \\
r_2 &: \mathbf{all}'(\mathbf{s}(\mathbf{I}), \mathbf{Y}, \mathbf{D}) \leftarrow \mathbf{all}(\mathbf{I}, \mathbf{Y}, \mathbf{D}), \mathbf{delta}'(\mathbf{s}(\mathbf{I}), _, _). \\
r_3 &: \mathbf{all}'(\mathbf{I}, \mathbf{Y}, \mathbf{D}) \leftarrow \mathbf{delta}'(\mathbf{I}, \mathbf{Y}, \mathbf{D}).
\end{aligned}$$

An XY-clique Q is said to be *XY-stratified* when

²This is only a matter of convention. Alternatively, we could let the last arguments of recursive predicates be our stage arguments.

- The primed version of Q is non-recursive
- All exit rules have as stage argument the same constant.

□

If Q is an XY -stratified clique, then Q is locally stratified, and computable using a simple fixpoint iteration [35].

In fact, observe that the primed dependency graph provides a very simple syntactic test on whether a program is XY -stratified. Furthermore these programs are amenable to very efficient implementation as proven in the following discussion. The primed version Q' of an XY -stratified clique defines a non-recursive program, and thus, it is stratifiable according to the predicate names. In particular, we want to consider a *topological layering* as follows: the bottom layer L_0 contains all the the unprimed predicate names, and the remaining layers L_1, \dots, L_n are singleton sets such that, for each rule r in Q' , the predicate names of the head of r belongs to layers strictly higher than those of the goals of r . For Example 16, the following is the only topological layering:

$$L_0 = \{\text{delta}, \text{all}\}, L_1 = \{\text{delta}'\}, L_2 = \{\text{all}'\}$$

The Herbrand Base of a recursive clique Q can now be partitioned into layers, where the atoms of non-recursive predicates form the bottom layer, and recursive atoms with the same predicate name and stage argument form the remaining layers. This partition can be ordered so that each atom with a lower stage argument belongs to lower layer than an atom with a higher stage argument, and if two atoms have the same stage argument, then the atom whose predicate name is first in the topological layering belongs to the lower layer. Now, our clique Q is strictly locally stratified, inasmuch as for each instantiated rule of Q , the goals belong to to layers that are strictly lower than the layer to which the head belongs. It thus follows that, (i) the perfect model of Q can be computed using an iterated fixpoint, and (ii) the fixpoint for each stratum is reached in one step. Therefore the computation of all atoms in the model sharing the same stage value is performed in n steps, where L_n denotes the last layer in the topological layering. Each of these steps involves the firing of all rules with the same head predicate name: thus having computed all the atoms with stage value of J , a *single pass through the rules of Q ordered according to the topological stratification of their heads* computes all the atoms with stage value $s(J)$.

Therefore, if Q is an XY -stratified clique, then (i) Q is locally stratified, and (ii) its perfect model can be constructed by a fixpoint iteration to the first ordinal: the recursive rules in the clique are fired according to the topological layering. In such a computation the stage arguments is projected out from each rule (the notation w.s.a. will denote a rule without its stage argument) [35]:

Perfect Model Computation for XY -stratified Cliques

Step 1. The stage variable is assigned the stage constant from the exit rules.

Step 2. Fire the X-rules (w.s.a), once

Step 3. Fire the recursive rules (w.s.a.) sequentially,

Therefore, the stage argument is updated only once per cycle. XY-stratified programs can express every program expressible under inflationary fixpoint [35].

3 Syntactic Encapsulation

New syntactic constructs introduced to replace frequently used expressions of First Order Logic can yield dramatic benefits in terms of readability and efficient implementation. For instance, the simple idea of encapsulating disjunctive clauses, with no more than one non-negated literal, by the basic rule notation yields the improvements in readability and amenability to efficient implementation that are at root of the popularity of the logic programming paradigm. The same method has been used with remarkable success in other situations. For instance, the choice construct was defined in [12] to capture the notion of don't care non-determinism and encapsulate certain kinds of negative programs amenable to a polynomial-time computation. Two other such constructs are `if-then(-else)` and `min/max` predicates, both used in the XY-stratified program below. This expresses Floyd's classic algorithm for computing the shortest paths in a graph:

Example 2 *Floyd Algorithm.*

```

delta(nil, X, X, 0).
delta(s(J), X, Z, min(< C >)) ← delta(J, X, Y, C1),
                                g(Y, Z, C2), C = C1 + C2.

all(s(J), X, Z, C) ← all(J, X, Z, C).
all(J, X, Z, C) ← delta(J, X, Z, C),
                  if(all(J, X, Z, C3) then C3 > C).

```

The `if-then` construct used in the last rule of Example 2, is a construct of \mathcal{LDL} and $\mathcal{LDL}++$ whose formal semantics is defined by its re-writing into a negative program: our rule is equivalent to

```

all(J, X, Z, C) ← delta(J, X, Z, C),
                  all(J, X, Z, C3), C3 > C.
all(J, X, Z, C) ← delta(J, X, Z, C),
                  ¬all(J, X, Z, C3).

```

Thus, programs containing if-then-else constructs are stratified iff their expansion using negation is.

Likewise, the notion of least elements in a set can be defined by the property that no lesser element exists. Take for instance the following rule from Example 2:

$$\begin{aligned} \text{delta}(s(J), X, Z, \min(\langle C \rangle)) \leftarrow & \text{delta}(J, X, Y, C1), \\ & g(Y, Z, C2), C = C1 + C2, \end{aligned}$$

Here $\langle C \rangle$ denotes the grouping of C values with respect to the other variables in the head; and \min denotes the least of such values. The meaning of this rule is defined by its equivalent expansion [11].

$$\begin{aligned} \text{delta}(s(J), X, Z, C) \leftarrow & \text{delta}(J, X, Y, C1), \quad g(Y, Z, C2), C = C1 + C2, \\ & \neg \text{lesser}(s(J), X, Z, C). \\ \text{lesser}(s(J), X, Z, C) \leftarrow & \text{delta}(s(J), X, Z, C'), \quad g(Y, Z, C2), C' = C1 + C2, \\ & C' < C. \end{aligned}$$

4 Semantics of Updates

Let us now consider a database language that, in addition to query requests, supports other commands, such as requests to add or delete some extensional facts. As shown in [27], the definition of the semantics of programs with updates need not make use of imperative constructs. Rather, defining the semantics of such a language tantamounts to defining the external behavior of programs written in this language. Neglecting for the moment integrity constraints, we see that the external response to an update command should basically be an acknowledgement of some sort (e.g., a carriage return). Thus, all it is left to do is to define the meaning of queries. However, there is a key difference with respect to standard framework of query-only logic-based semantics [17, 30]: here we must specify the answer to queries *after the database has been modified by a given sequence of updates*. Thus, in our formal model we have (i) a program P containing a set of rules and a schema describing the extensional database, (ii) a set of extensional facts D defining the initial database state (iii) a sequence of update requests R , and (iv) a query Q ; then we must define the *meaning function* $M(P, D, R, Q)$. For instance, consider the following example

Example 3 *We assume that our program P contains the declaration of two database relations `std`, `grad` (describing the majors and the courses and grades of students) and the following rule:*

$$\text{csst}(X, C) \leftarrow \text{std}(X, \text{cs}), \text{grad}(X, C, _).$$

The initial database D contains the following facts:

$$\begin{aligned} \text{std}(\text{ann}, \text{ee}). \quad & \text{grad}(\text{ann}, \text{cs143}, 3). \\ \text{std}(\text{tom}, \text{cs}). \end{aligned}$$

R , the set of update requests, is:

$$\begin{aligned} \text{req}(1, \text{add}, \text{std}(\text{marc}, \text{ee})). \\ \text{req}(2, \text{del}, \text{std}(\text{ann}, \text{ee})). \\ \text{req}(2, \text{add}, \text{std}(\text{ann}, \text{cs})). \end{aligned}$$

The query is: $?csst(X, Y)$.

We have represented our sequence of update requests as a relation `req`; the first argument in `req` places the particular request in the proper time sequence. Successive requests are given successive integers by the system. However, several requests can be given the same sequence number, to ensure that they are processed in parallel. For instance, the last two entries in R model a user-level request to modify the major of Ann from EE to CS.

We need a logic-based semantics to compute the correct answer to a query such as `?csst(X, Y)`, given a certain initial database and an arbitrary sequence of updates. Since a query can inquire about the content of any relation after a sequence of such updates, we will have to model the notion of states our database goes through; however, we must avoid destructive assignments in order to remain declarative. To obtain this goal, we use a distinguished predicate `quevt` that, basically, operates as a queue of events. For now, the `quevt` predicate can be thought of as performing a copy of the `req` predicate as follows.

Example 4 *A first attempt at quevt*

$$\text{quevt}(N, \text{Typ}, \text{Atom}, N) \leftarrow \text{req}(N, \text{Typ}, \text{Atom}).$$

The meaning of a program P with external updates is thus defined by generating an equivalent program P' . For each extensional predicate q/n we now define a new intensional predicate $q/n + 1$ (we assume without loss of generality that there is no $q/n + 1$ in the original P .) These new intensional predicates are defined recursively, by XY-stratified programs:

Example 5 *From Extensional Predicates to XY-stratified programs.*

$$\begin{aligned} \text{std}(0, X1, X2) &\leftarrow \text{std}(X1, X2). \\ \text{std}(J + 1, X1, X2) &\leftarrow \text{quevt}(J + 1, -, -, -), \text{std}(J, X1, X2), \\ &\quad \neg \text{quevt}(J + 1, \text{del}, \text{std}(X1, X2), -). \\ \text{std}(J + 1, X1, X2) &\leftarrow \text{std}(J, -, -), \text{quevt}(J + 1, \text{add}, \text{std}(X1, X2), -). \end{aligned}$$

$$\begin{aligned} \text{grad}(0, X1, X2, X3) &\leftarrow \text{grad}(X1, X2, X3). \\ \text{grad}(J + 1, X1, X2, X3) &\leftarrow \text{quevt}(J + 1, -, -, -), \text{grad}(J, X1, X, X3), \\ &\quad \neg \text{quevt}(J + 1, \text{del}, \text{grad}(X1, X2, X3), -). \\ \text{grad}(J + 1, X1, X2, X3) &\leftarrow \text{grad}(J, -, -), \text{quevt}(J + 1, \text{add}, \text{grad}(X1, X2, X3), -). \end{aligned}$$

Furthermore, the old rules of P are replaced with new ones, obtained from the old ones by adding a stage argument to every predicate in the rules:

Example 6 *Rewriting the original rules*

$$\text{csst}(J, X, C) \leftarrow \text{std}(J, X, \text{cs}), \text{grad}(J, X, C, -).$$

The query goal $?sst(S, C)$ is then modified in an obvious way. To find the proper answer to the query after the first request $req(1, add, std(marc, ee))$, we pose the query: $?csst(1, S, C)$. But, the correct answer to the same query after the next two requests have been serviced is produced by $?csst(2, S, C)$.

Thus, we replaced the old predicates with new ones containing an additional stage argument. For notational convenience we shall represent the stage as a superscript; thus instead of writing $std(J, X, cs)$ we write $std^J(X, cs)$. Thus a new program P' is constructed from the original one P by replacing the old rules of P with new ones where the predicates are stage-superscripted. Moreover, for each extensional predicate q of P , P' contains the following set of XY-stratified rules:

Example 7 *Intensional Updates*

$$\begin{aligned}
r_1 : q^0(\mathbf{X}) &\leftarrow q(\mathbf{X}). \\
r_2 : q^{J+1}(\mathbf{X}) &\leftarrow quevt^{J+1}(-, -, -), q^J(\mathbf{X}), \\
&\quad \neg quevt^{J+1}(del, q(\mathbf{X}), -). \\
r_3 : q^{J+1}(\mathbf{X}) &\leftarrow q^J(\mathbf{X}), quevt^{J+1}(add, q(\mathbf{X}), -).
\end{aligned}$$

These three rules will be called, respectively as follows: r_1 the *base rule*, r_2 the *copy-delete rule*, and r_3 the *add rule*. Then, the deletion-copy rule copies the old relation into a new one, modulo any deletion that is currently pending on the event queue $quevt$. The insert rule services the add requests currently pending in $quevt$. The base rule defines a derived predicate with stage value of zero, for each extensional predicate.³

The resulting program P' is XY-stratified and defines the meaning of the original program P . The correct answer to query $?q(\mathbf{X})$ once all the req^J entries have been serviced is simply the answer to $?q^J(\mathbf{X})$. For instance, with P, D and R defined in Example 4, the perfect model of our modified program P' contains the following derived facts:

Example 8 *The perfect model for P' (derived facts only)*

$$\begin{array}{lll}
std^0(tom, cs) & grad^0(ann, cs143, 3) & \\
std^0(ann, ee) & & \\
std^1(tom, cs) & grad^1(ann, cs143, 3) & \\
std^1(ann, ee) & & \\
std^1(marc, ee) & & \\
std^2(tom, cs) & grad^2(ann, cs143, 3) & csst^2(ann, cs143) \\
std^2(marc, ee) & & \\
std^2(ann, cs) & &
\end{array}$$

A query, such as $?csst(S, C)$, is then changed into $?csst^2(S, C)$ and answered against such a perfect model.

This simple rendering of the semantics of updates captures one intuitive understanding of these operations. It also is suggestive of efficient operational semantics. In

³We assume that initially our database relations are not empty. Otherwise, an additional exit rule, $p^0(nil) \leftarrow \neg p(\mathbf{X})$, can be added.

fact, delete-copy rules can be implemented with the update-in-place policy, outlined for XY-programs, whereby records are simply added to, or deleted from, the current copy of the relation. The declarative semantics of these rules is, however, fully retained, as demonstrated by the fact that queries corresponding to update subsequences are also supported: it is also possible to pose queries such as $\text{csst}^0(\mathbf{S}, \mathbf{G})$ or $\text{csst}^1(\mathbf{S}, \mathbf{G})$.

Integrity constraints could also be treated in this framework. If the enforcement policy consists in rejecting any request that violates the constraint (e.g., rejecting a request for insertion of a new tuple violating a key constraint), then the proper checking conditions can be attached to the rule defining `quevt`. Policies where violations are corrected by additional actions (e.g., elimination of dangling foreign key references) can be supported using the condition-action rules or the event-action rules discussed next.

5 Condition-Action Rules

Say that we want to enforce a rule such as: If a student has taken both cs10 and cs20, then he or she is considered having CS as major. For that, we could write:

$$\text{add}(\text{std}(\mathbf{S}, \text{cs})) \leftarrow \text{grad}(\mathbf{S}, \text{cs10}, -), \text{grad}(\mathbf{S}, \text{cs20}, -).$$

Another possible rule could enforce a deletion dependency whereby one will want to delete the classes taken by students that are not longer enrolled. This can be accomplished as follows:

$$\text{del}(\text{grad}(\mathbf{S}, \mathbf{C}, \mathbf{G})) \leftarrow \text{grad}(\mathbf{S}, \mathbf{C}, \mathbf{G}), \neg \text{std}(\mathbf{S}, -).$$

This simple example also illustrates the need for a formal semantics. In fact assume that a request is placed to introduce both a cs20 and a cs10 record for a given student. Then, according to intuition alone, each of the following alternatives appears plausible: (i) an insertion of a new cs student or (ii) the deletion of all the courses this student has taken, or (iii) both such actions, or (iv) neither action, or (v) an infinite loop. After the introduction of a formal semantics, only one of these alternatives will be considered correct (in the semantics discussed next it is iii).

The semantics we propose for active rules, views `del` and `add` as built-in derived predicates. Thus these two rules are simply re-written as any other rule:

$$\begin{aligned} \text{add}^J(\text{std}(\mathbf{S}, \text{cs})) &\leftarrow \text{grad}^J(\mathbf{S}, \text{cs10}, -), \text{grad}^J(\mathbf{S}, \text{cs20}, -). \\ \text{del}^J(\text{grad}(\mathbf{S}, \mathbf{C}, \mathbf{G})) &\leftarrow \text{grad}^J(\mathbf{S}, \mathbf{C}, \mathbf{G}), \neg \text{std}^J(\mathbf{S}, -). \end{aligned}$$

Furthermore, there is no change in the intensional update rules for the extensional predicates. However, the rules defining `quevt` must be extended to account for the `add` and `del` predicates as follows:

Example 9 *An improved definition for quevt*

$$\begin{aligned}
\text{quevt}^{J+1}(\text{add}, W, N) &\leftarrow \text{quevt}^J(-, -, N), \text{add}^J(W). \\
\text{quevt}^{J+1}(\text{del}, W, N) &\leftarrow \text{quevt}^J(-, -, N), \text{del}^J(W). \\
\text{quevt}^{J+1}(X, W, N + 1) &\leftarrow \text{quevt}^J(-, -, N), \\
&\quad \neg\text{add}^J(-), \neg\text{del}^J(-), \\
&\quad \text{req}^{N+1}(X, W).
\end{aligned}$$

Thus, active rules will add to the `quevt` table. Once these rules have stopped firing, then new external requests from `req` can further expand the table.

After a sequence of n requests, the correct answer to query $?q(\mathbf{X})$, is obtained by answering the following three goals

$$? \text{quevt}^J(-, -, n), \neg \text{quevt}^{J+1}(-, -, n), q^J(\mathbf{X})$$

Thus, one needs to find the highest stage value J reached after input n ; the correct answer is derived from predicates $p^J(\mathbf{X})$.

Condition-action rules are very powerful, and can be used in several applications, including constraint maintenance or truth-maintenance support [2]. On the other hand, condition-action rules can be expensive to support since they require the recomputation of the body of each rule every time a new update occurs in the base relations defining such a rule. Thus, every database predicate appearing in the body of an active rule must be monitored for changes; for derived predicates, possibly recursive ones, the derivation tree (dependency graph) must be traced down to the database predicates involved. While differential methods, such as the semi-naive fixpoint and truth-maintenance techniques, can be exploited in this context, it is also clear that condition-action rules tend to be complex and expensive to support. For these reasons, more recent systems favor an alternative approach where the events that can trigger the firing of the rules are stated explicitly in the bodies of the rules.

6 Event-Action Rules

In systems such as Postgres [29], the events upon which a rule fires are stated explicitly. These rules can be easily modeled in our framework. For instance, the previous active rules involving students and courses could be expressed as follows:

Example 10 *Event-driven rules*

$$\begin{aligned}
\text{add}(\text{std}(S, \text{cs})) &\leftarrow \text{add}(\text{grad}(S, \text{cs10}, -)), \text{grad}(S, \text{cs20}, -). \\
\text{add}(\text{std}(S, \text{cs})) &\leftarrow \text{grad}(S, \text{cs10}, -), \text{add}(\text{grad}(S, \text{cs20}, -)). \\
\text{del}(\text{grad}(S, -, -)) &\leftarrow \text{del}(\text{std}(S, -)).
\end{aligned}$$

These event-driven rules are easily supported in our framework. We basically interpret event-action rules as stating that, when `add` or `del` events are queued in the `quevt` relation, then, the `add` or `del` predicates are enabled (requested). Thus, the meaning of the previous rules is defined by the following re-writing:

Example 11 *Expansion of event-driven rules*

$$\begin{aligned} \text{add}^J(\text{std}(\text{S}, \text{cs})) &\leftarrow \text{quevt}^J(\text{add}, \text{grad}(\text{S}, \text{cs10}, -), -), \text{grad}(\text{S}, \text{cs20}, -). \\ \text{add}^J(\text{std}(\text{S}, \text{cs})) &\leftarrow \text{grad}(\text{S}, \text{cs10}, -), \text{quevt}^J(\text{add}, \text{grad}(\text{S}, \text{cs20}, -), -). \\ \text{del}^J(\text{grad}(\text{S}, -, -)) &\leftarrow \text{quevt}^J(\text{del}, \text{std}(\text{S}, -, -)). \end{aligned}$$

By the definition of `quevt`, these `add` and `del` requests queued at stage J will be executed at stage $J + 1$.

7 Event-Based Programming

New events can be defined in addition to the basic `add`, `del` ones and used in various roles, including constraint management and application programming. As a (somewhat contrived) example, for instance, say that we want to raise the grades of Ann until her grades are all greater or equal to 4. This will be accomplished by the definition of a new `raise` event,

Example 12 *Raising the grades of students*

$$\begin{aligned} \text{del}(\text{grad}(\text{S}, \text{C}, \text{G})) &\leftarrow \text{evt}(\text{raise}(\text{S})), \text{grad}(\text{S}, \text{C}, \text{G}), \text{G} < 4. \\ \text{add}(\text{grad}(\text{S}, \text{C}, \text{G}')) &\leftarrow \text{evt}(\text{raise}(\text{S})), \text{grad}(\text{S}, \text{C}, \text{G}), \text{G} < 4, \text{G}' = \text{G} + 1. \\ \text{evt}(\text{raise}(\text{S})) &\leftarrow \text{evt}(\text{raise}(\text{S})), \text{grad}(\text{S}, \text{C}, \text{G}), \text{G} < 4. \end{aligned}$$

followed by the request: `evt(raise(ann))`. These rules, with $\text{S} = \text{ann}$ are now executed in parallel enabling the corresponding set of events. These are then enqueued by the following `quevt` rules:

Example 13 *The final definition of quevt*

$$\begin{aligned} \text{quevt}^{J+1}(\text{add}, \text{W}, \text{N}) &\leftarrow \text{quevt}^J(-, -, \text{N}), \text{add}^J(\text{W}). \\ \text{quevt}^{J+1}(\text{del}, \text{W}, \text{N}) &\leftarrow \text{quevt}^J(-, -, \text{N}), \text{del}^J(\text{W}). \\ \text{quevt}^{J+1}(\text{ev}, \text{W}, \text{N}) &\leftarrow \text{quevt}^J(-, -, \text{N}), \text{ev}^J(\text{W}). \\ \text{quevt}^{J+1}(\text{X}, \text{W}, \text{N} + 1) &\leftarrow \text{quevt}^J(-, -, \text{N}), \\ &\quad \neg \text{add}^J(-), \neg \text{del}^J(-), \neg \text{ev}^J(-), \\ &\quad \text{req}^{\text{N}+1}(\text{X}, \text{W}). \end{aligned}$$

Then, event-action rules can be re-written as follows:

Example 14 *Raising the grades of students*

$$\begin{aligned} \text{del}^J(\text{grad}(\text{S}, \text{C}, \text{G})) &\leftarrow \text{quevt}^J(\text{evt}, \text{raise}(\text{S}), -), \text{grad}^J(\text{S}, \text{C}, \text{G}), \text{G} < 4. \\ \text{add}^J(\text{grad}(\text{S}, \text{C}, \text{G1})) &\leftarrow \text{quevt}^J(\text{evt}, \text{raise}(\text{S}), -), \text{grad}^J(\text{S}, \text{C}, \text{G}), \text{G} < 4, \text{G1} = \text{G} + 1. \\ \text{evt}^J(\text{raise}(\text{S})) &\leftarrow \text{quevt}^J(\text{evt}, \text{raise}(\text{S}), -), \text{grad}^J(\text{S}, \text{C}, \text{G}), \text{G} < 4. \end{aligned}$$

The detection of an event condition $\text{ev}(\text{raise}(\mathbf{S}))$ results in the checking of additional conditions and in the setting of a new event, including the re-setting of the old event $\text{ev}(\text{raise}(\mathbf{S}))$, as illustrated by the last rule above. All applicable rules are fired in parallel; it is thus possible to perform recursive programming, whereby the same action is repeated while the body conditions remain true. The action performed at each step can be a basic update, or some other action, including the invocation of a query or the printing of some results.

8 Conclusion

The semantic framework here proposed yields the design of a rule-based language capable of addressing both the active and deductive aspects of programming. For deductive rules, one can keep the basic framework of Horn Clauses, with non-monotonic extensions, including negation and aggregates under the XY-stratification assumption. Active rules can be specified with the same syntax, provided that **add**, **del**, **evt** are built-in predicates. A uniform perfect-model semantics is ensured by the re-writing methods just discussed, which do not rely on meta-level or higher order constructs.

Building on this semantic bedrock, the language designer can consider further improvements and structuring of the language to improve the efficiency and clarity of programs. For instance, practical considerations might suggest that condition-action rules should be disallowed; in this case, the language will only support two kinds of rules. The first kind of rules are deductive ones without any event predicate. The other kind consists of event-action rules: these are defined as having an event predicate in their head, and one or more positive event goals in their bodies. Syntactic sugaring conventions might also be used to improve the expressivity of the language. A simple improvement would allow rules with multiple heads as a short-hand for several rules with similar bodies. The previous example, for instance, could be abbreviated as follows:

Example 15 *A multi-head rule.*

$$\begin{array}{l} \text{del}(\text{grad}(\text{ann}, \mathbf{C}, \mathbf{G})), \\ \text{add}(\text{grad}(\text{ann}, \mathbf{C}, \mathbf{G1})), \\ \text{evt}(\text{raise}(\mathbf{S})) \leftarrow \quad \text{evt}(\text{raise}(\mathbf{S})), \\ \quad \quad \quad \text{grad}(\mathbf{S}, \mathbf{C}, \mathbf{G}), \mathbf{G} < 4, \mathbf{G1} = \mathbf{G} + 1. \end{array}$$

Also observe that that within the power and uniformity provided by such a language, there will be specialized usages. For instance, a system administrator will be predominantly concerned with monitoring events such such as **add** and **del**. However, application programmers will be mostly interested in defining new event types that will be invoked by certain classes of users. Each such application is defined by an event that is invoked by a user request or triggered by other applications. Each application can call itself recursively, or can take various actions, including calling other applications.

A new rule-based language incorporating these principles is currently being designed at UCLA.
